

Role of Disorder in the Thermodynamics and Atomic Dynamics of Glasses

Aleksandr Chumakov*¹

¹European Synchrotron Radiation Facility

The heat capacity of glasses at temperatures of about ~ 10 K for a long time was considered to be anomalously higher than that of the corresponding crystals. The related excess of the low-energy vibrational states, the so-called 'boson' peak, was similarly considered to be an anomaly distinguishing glasses from crystals and related to their disordered state. Recent results [1] reveal that (i) the difference in the discussed properties occurs not because the glass is structurally disordered, but because it usually has lower density than that of the corresponding crystal, (ii) the heat capacity of glasses and crystals with same densities is quite similar, and (iii) the boson peak is the glassy counterpart of the van Hove singularity of the corresponding crystal.

We analyze the generality of the new results and discuss the compatibility of the suggested interpretation of the boson peak with available experimental data. Analyzing the relation of the new results to various theoretical models, we discuss a possible experimental approach to explore further the nature of the low-frequency vibrational excitations in glasses [2].
